ABSTRACT

Do infants develop meaningful social preferences among novel individuals based on their social group membership? If so, do these social preferences depend on familiarity on any dimension, or on a more specific focus on particular kinds of categorical information? The present experiments use methods that have previously demonstrated infants' social preferences based on language and accent, and test for infants' and young children's social preferences based on race. In Experiment 1, 10-month-old infants took toys equally from own- and other-race individuals. In Experiment 2, 2.5-year-old children gave toys equally to own- and other-race individuals. When shown the same stimuli in Experiment 3, 5-year-old children, in contrast, expressed explicit social preferences for own-race individuals. Social preferences based on race therefore emerge between 2.5 and 5 years of age and do not affect social choices in infancy. These data will be discussed in relation to prior research finding that infants' social preferences do, however, rely on language: a useful predictor of group or coalition membership in both modern times and humans' evolutionary past.

1. Introduction

Adults' social interactions with novel individuals are guided not only by the actions of those individuals, but also by the social categories to which they belong. Adults particularly attend to gender, race and age in evaluating people (Fiske, 1998), and their social judgments are influenced by others' language and accent as well (Giles & Billings, 2004; Gluszek & Dovidio, 2010). Research in developmental psychology suggests that category-based social preferences emerge early in development, and raises questions concerning the processes that produce these preferences. The present research attempts to shed light on the processes governing children's social category-based preferences by assessing infants' and young children's social preferences based on race, in relation to prior work demonstrating young children's preferences based on language and accent.

On one theory, infants and children tend to prefer people whose properties are most familiar to them. Familiarity, in this case, is not limited to or defined by any particular domain. Indeed, human preferences for the familiar are observed for non-social stimuli such as line drawings, polygons or words, as well as for social stimuli such as faces (Bornstein, 1989; Harrison, 1969; Rhodes, Halberstadt, & Brajkovich, 2001; Zajonc, 1968, 2001). An early preference for the familiar might be adaptive given that entities that are familiar could, on average, be safer than the unknown. On a different theory, human social preferences might reflect preferences for and reasoning about social kinds (e.g., a naïve sociology that differs from reasoning about non-human kinds; Hirschfeld, 1996). These early preferences for human kinds might even originate in a more specific, evolved, sensitivity to information that distinguished between categories of people within and across social groups throughout our evolutionary history. Within a single social community, all societies in all times are composed of individuals of varying gender, age, and kinship relationships, and so these factors may be

particularly psychologically prominent (Cosmides, Tooby, & Kurzban, 2003; Kurzban, Tooby, & Cosmides, 2001; Lieberman, Oum, & Kurzban, 2008). Throughout ancient times, patterns of cooperation and competition would have served as good predictors of coalitional group membership across different social groups, and young children attend to these factors today (Cosmides et al., 2003; Fehr, Bernhard, & Rockenbach, 2008; Olson & Spelke, 2008; Rhodes & Brickman, *in press*). Given the speed with which languages and accents evolve, and the apparent difficulty with which we learn a non-native accent as adults, language, too, may have served as a valid predictor of native group membership throughout our evolutionary history (Baker, 2001; Henrich & Henrich, 2007; McElreath, Boyd, & Richerson, 2003; Pietraszewski & Schwartz, 2007). Though race-based social categorization is certainly apparent in adults today, the aspects of visual appearance that distinguish members of different racial groups today were likely of little value in distinguishing members of neighboring coalitions in ancestral environments, prior to the onset of long-distance migration (Cosmides et al., 2003; Kurzban et al., 2001). Thus, though race may be an indicator of coalition in many societies today, we likely did not evolve to see race *per se* as a marker of group membership, and infants and young children may not intuitively award social importance to racial group membership.

Research with children provides some support both for the presence of early familiarity preferences, and also for young children's more specific preferences for certain social categories. First, considering preferences for familiar social others more generally, young infants' visual preferences for the faces of novel individuals have been linked to the familiarity of the face categories. Infants of African descent look longer at own-race (Black) faces than at other-race (White) face if they reside in Africa, in a community in which faces of their race predominate, but Ethiopian infants born in Israel look equally to Black and White faces (Bar-Haim, Ziv, Lamy, & Hodes, 2006; see also, Kelly et al., 2005). Moreover, infants look longer at female faces than male faces if their primary caretaker is female, but may not show this preference if their primary caretaker is male (Quinn, Yahr, Kuhn, Slater, & Pascalis, 2002; Ramsey-Rennels & Langlois, 2006); furthermore, 3-month-old infants display visual preferences based on gender only when tested with faces of a familiar race (Quinn et al., 2008). By preschool age, children often demonstrate social preferences for individuals of their own gender, race, and age (Aboud, 1988; Alexander & Hines, 1994; Baron & Banaji, 2006; French, 1984; Katz & Kofkin, 1997; Kircher & Furby, 1971; Kowalski & Lo, 2001; Maccoby & Jacklin, 1987). Moreover, children's preferences for the familiar may underlie the finding that in-group preferences based on race are stronger for majority-race children than for minority-race children (Cameron, Alvarez, Ruble, & Fuligni, 2001). Finally, 5–6 month-old infants look longer at the face of a person who had previously spoken in their native language with a native accent, relative to a second person who previously spoke in a foreign language or accent (Kinzler, Dupoux, & Spelke, 2007). Nevertheless, in each of the cases described above depicting infant research, it is not clear whether looking patterns

in infancy are reflective of rich social preferences, or instead may reflect perceptual processing advantages, without any obligatory social meaning.

Though children demonstrate preferences for the familiar based on multiple dimensions, children's early social responses also reflect priorities in the importance they grant to different social categories (Kinzler, Shutts, & Correll, 2010). Children show social preferences for same-gender children by 2–3 years of age (e.g., Jacklin & Maccoby, 1978; LaFreniere, Strayer, & Gauthier, 1984); nevertheless, race-based preferences do not reliably emerge until closer to 4 or 5 years of age (Abel & Sahinkaya, 1962; Aboud, 2003; Brown & Johnson, 1971; Kircher & Furby, 1971; Stevenson & Stewart, 1958). In a recent study, Shutts, Banaji, and Spelke (2010) directly compared the influence of gender, race and age on 3-year-old children's preferences for novel objects or activities that were endorsed by unfamiliar people who varied in gender, race and age. Gender and age, but not race, were robust guides to children's choices. Similarly, 5-year-old children express beliefs that gender categories, but not race categories, are objectively and biologically determined (Rhodes & Gelman, 2009). Finally, though children demonstrate both native-accent and own-race preferences when each category is tested separately (Aboud, 1988; Kinzler et al., 2007), when the two categories are put in conflict such that accent is pitted against race, children prefer native-accented other-race individuals to foreign-accented own-race individuals (Kinzler, Shutts, DeJesus, & Spelke, 2009). To tease apart the forces that drive children's developing social preferences and potential priorities that emerge in children's social categorization, it will be important to study the emergence of these preferences in younger infants.

Do infants develop meaningful social preferences among novel individuals? If so, do these preferences depend on the relative familiarity of those individuals on any dimension, or do they depend on a more specific focus on particular kinds of categorical information? Recent research begins to address this question by focusing on infants' social engagement with speakers of different languages and accents. In a series of studies, 10-month-old infants in the US and France were shown movies of a native French speaker and a native English speaker who spoke to the infant in alternation. Infants then were shown events in which the two speakers appeared together without speaking, held up two identical toys and, silently and in synchrony, offered the toys to the infant. Just at the moment at which the toys disappeared from view, two real toys appeared in front of the infant, giving the illusion that the toys came from the screen. Infants in the US reached for the toy offered by an English speaker rather than a French speaker, and infants in France reached for the toy offered by the French speaker, even though the toys were identical and were never paired on screen with the language (Kinzler et al., 2007). Prior to speaking themselves, therefore, infants chose to interact with a native speaker of their native language.

Further research provides evidence that social preferences for native speakers persist in later childhood and guide even more explicit social decisions. In one study, 2.5-year-old children were shown the same displays of

French and English speakers. The two speakers then appeared together silently, and children were given an opportunity to “give a present” to one of them. Children in both the US and France reliably chose the native speaker as the recipient of their gift (Kinzler, Dupoux, & Spelke, *in press*). In another study, 5-year-old children viewed still photographs of children and listened to samples of their speech, which varied either in language or in accent. Children were asked to choose one child as a friend. Their choices were reliably affected by the accent with which the other children spoke. Moreover, children’s friendship choices dissociated from their judgments of comprehensibility: although children understood a child who spoke their native language with a foreign accent, they nonetheless preferred to associate with a native-accented child (Kinzler et al., 2009).

The above studies provide tools that can be used to probe the origins and nature of social categories, and find signatures of social preferences that go beyond measures of looking time in infancy. Beyond its potential evolutionary significance, language might be considered a particularly good candidate for eliciting social preferences early in development. From birth, infants prefer the sound of their native language to a foreign language, and discriminate two foreign languages if they cross a rhythmic boundary (Mehler et al., 1988; Nazzi, Bertoncini, & Mehler, 1998; Weikum et al., 2007). By 5 months of age, infants successfully discriminate two languages or dialects within the same rhythmic class, provided that one of the languages is their own (Bosch & Sebastián-Gallés, 1997; Nazzi, Jusczyk, & Johnson, 2000). Beyond the literal communication it provides, spoken language also offers information about individuals’ nationality, regional membership, ethnic group, and social status or class (Gluszek & Dovidio, 2010; Labov, 2006). Indeed, adults use the language and accent of individuals that they have never met to infer not just the origins of those individuals, but also their intelligence, warmth, and even height (see Giles and Billings (2004) for a review).

Language, however, is not alone in marking social groups in modern times. Language and race are similar in dividing the human social world into groups with high intra-group and low inter-group contact. Both categories elicit looking preferences for the familiar in infants (Bar-Haim et al., 2006; Kelly et al., 2005; Kinzler et al., 2007), and within the first year of life infants evidence better face recognition of familiar compared to unfamiliar-race faces (Kelly et al., 2007; Sangrigoli & de Schonen, 2004). By the end of the preschool years, children reliably express race-based social preferences and inferences (e.g., Aboud, 1988; Baron & Banaji, 2006; Cameron et al., 2001). And, research from social psychology has provided manifest evidence of fast, automatic, and effortless encoding of race as part of person perception in adulthood, with myriad cognitive and social consequences (e.g., Dovidio, Kawakami, & Gaertner, 2002; Hodson, Dovidio, & Gaertner, 2002; Ito & Urland, 2003; Macrae & Bodenhausen, 2000; Meissner & Brigham, 2001; Pettigrew & Meertens, 1995). Thus, if the development of social preferences stems from differences observed in any dimension of social familiarity that infants can perceptually discriminate, or from social

group distinctions that are marked in adulthood in modern times, then majority-race infants and young children should show social preferences based not only on language, but also on race. In contrast, if infants’ earliest social preferences rely in part on attention to factors that distinguished groups throughout evolutionary history, then infants may not award the same social importance to race as they do language.

In the present research, we borrow methods previously used to test social preferences based on language, and employ them to test for early social preferences based on race. Three measures that previously revealed infants’ and children’s social preferences based on language were used to test the emergence of race-based social preferences throughout early childhood: toy choices at 10 months (Kinzler et al., 2007), toy giving at 2.5 years (Kinzler et al., *in press*), and explicit judgments at 5 years (Kinzler et al., 2009). In all three of the studies presented here, children were shown the same videotaped events involving one Black and one White female who smiled and, in some conditions, spoke with the child’s native language and accent.

The present studies tested the race-based social preferences only of majority-race, White infants. We did not test minority-race infants, because the familiarity theory of social preferences makes no clear predictions concerning the preferences of such infants, for whom faces of both races are likely to be highly familiar (Bar-Haim et al., 2006; see also Aboud & Skerry, 1984). Moreover, although past research has shown preferences for native language speakers in infants for whom the native language is also the country’s predominant language (e.g. English in the US and French in France), we do not know if the same preferences would be shown by infants whose families speak a minority language. To maximize the similarity of the present tests of race preferences to previous tests of language preferences, therefore, we focused only on infants of the majority-race (White) in their communities.

Experiment 1 presented White 10-month-old infants with an interactive “toy choice” in which toys were offered to infants by individuals who were either their own race (White), or another race (Black), and infants’ choices were measured. Experiment 2 used the same displays to test 2.5-year-old children’s selective giving of toys to own-race vs. other-race individuals. Experiment 3 presented White 5-year-old children with the same test displays as shown to infants and toddlers, and assessed children’s explicit social preferences towards own- and other-race individuals.

2. Experiment 1

Experiment 1 borrowed the method of Kinzler et al. (2007), which tested infants’ early social preferences based on language, to assess infants’ preferences for social interactions based on race. White 10-month-old infants were presented with videos of a White and a Black individual who each offered identical toy objects to the infant. An illusion was created such that the toys appeared to emerge from the screen, and landed on the table in front of the infant. Infants’ manual choices of objects were measured.

Because past research using this method revealed a strong effect of native language on infants' toy choices, it was important to equate the speech of the two individuals. Nevertheless, a question arises as to whether to present the individuals in a speech context. It is possible that the presence of language in these videotapes would enhance any social effect of race, because the opportunity to hear both people speak might heighten infants' attention to the people and their contrasting properties. Alternatively, given that speech may provide infants with evidence that each speaker is a member of their native community, social preferences between individuals of different races may be stronger when the individuals are silent and their language status is ambiguous. Accordingly, half of the infants in this experiment were tested with individuals who were silent (but friendly) throughout the study, and the remaining infants were tested with individuals who both spoke to infants in their native language.

2.1. Method

2.1.1. Participants

Twenty-four full-term White 10-month-old infants participated in the study (14 females; mean age 10 months 13 days; range 9 months 23 days–11 months 2 days). Data from 1 additional subject were excluded due to failure to make a choice on any trial.

2.1.2. Materials

The stimuli were modeled after those from Kinzler et al. (2007). The toy choice films depicted the two speakers (one White female, one Black female) simultaneously on screen, each holding an identical toy animal, smiling at the toy, and then smiling at the infant and lowering the toy as if offering it to the infant (19 s; Fig. 1). The White actress was featured in Kinzler et al. (2007). The Black actress was identified by adult raters to be clearly of African descent. The films were projected approximately life-size on a screen that measured 92 × 122 cm, behind a 50 cm table. The speaking trials consisted of each individual speaking to the baby in native child-directed speech for 10 s (in a 13-second total film).

2.1.3. Design and procedure

On each of four test trials, infants saw a toy choice event, with both White and Black individuals pictured simultaneously offering a toy to the infant. Just at the moment when the toys disappeared off screen, two real toys "magically" appeared from behind the table for the infant to grasp, giving the illusion that they emerged from the screen. The objects were attached by Velcro to PVC piping that rotated from behind the table, and landed on the table equidistant from the infant and in front of the silent and motionless images of the two individuals. Half of participants saw only these four toy choice events; half of participants saw each toy offering event preceded by speaking trials, in which each individual engaged in infant-directed native speech. The ordering and lateral positions of the White and Black individuals were counterbalanced across infants in each condition, and the individuals reversed sides after the second trial. Infants' first reach during a

Fig. 1. Images of the White and Black actresses in Experiment 1. These same individuals were featured in all three experiments.

15-s period was recorded by an observer who was blind to the lateral position of individuals on each trial. Data for any infant who reached on at least one of the four trials, and watched the relevant offering event, were included. Data were analyzed by a repeated-measures ANOVA comparing number of choices of the toy offered by the White and Black individual.

2.2. Results

In both the speaking and the silent conditions, infants accepted toys about equally from the individuals of the two races; if anything, they showed a slight preference for the Black individual (Fig. 2, left). A repeated-measures ANOVA comparing number of choices for the toy offered by the White individual vs. number of choices for the toy offered by the Black individual as a within-subjects variable, and condition (speaking or silent) as a between-subject variable, revealed that infants had no significant preference to accept a toy from the White or Black individual ($M_{\text{White}} = 1.29$, $SE = .22$; $M_{\text{Black}} = 1.66$; $SE = .20$, $F(1, 22) = 1.23$, $p = \text{n.s.}$), with no main effect of condition ($F(1, 23) = .25$, $p = \text{n.s.}$), and no interaction of race with condition ($F(1, 22) = 1.23$, $p = \text{n.s.}$). A binomial non-parametric test confirmed this result: 11 children took more toys from the Black individuals, 6 children took more toys from the White individual, and 7 children took toys equally ($p = \text{n.s.}$, 2-tailed sign test).

2.3. Discussion

In contrast to infants' preferences for interactions based on language (Kinzler et al., 2007), infants did not

Fig. 2. Number of trials on which infants and children chose the White or Black individual in Experiment 1 (left), 2 (center) and 3 (right). Error bars represent standard error.

preferentially accept toys from own-race individuals. Although young infants' looking patterns in previous research provide evidence of attention to race (Bar-Haim et al., 2006; Kelly et al., 2005), the present finding suggests that early looking patterns may not necessarily reflect deeper social predilections that are present prior to an infant's first birthday. Looking preferences may evidence low-level visual preferences for familiar faces that are not consistent with social discriminations. Relative familiarity of any ilk, thus, may not equally compel early preferences for social interactions as measured on this task.

It should be noted that 10 months of age just precedes the time when infants are beginning to speak. Perhaps the nature of early language learning places a great emphasis on attention to native speakers, and slightly older, more linguistically sophisticated children would attend to both language and race in guiding their social preferences. Moreover, given that race-based social preferences are shown to emerge during the preschool years (e.g. Aboud, 1988), it is plausible that such preferences might be found by the end of toddlerhood. Experiment 2 therefore tested 2.5-year-old children's social giving, which has been shown in past work to be an age-appropriate measure of social preferences in toddlers for native, compared to foreign speakers.

3. Experiment 2

Experiment 2 investigated toddlers' preferences for own- vs. other-race individuals by means of a "magical giving game," (after Kinzler et al., *in press*). Children were given an object described as a "present" and were shown that they could place it in a box to give to one of two cartoon characters, as training. When they did so, the toy subsequently appeared on screen in front of the character whose box the child had chosen. Once children understood the game, the characters were replaced by images from the videotapes used in Experiment 1, depicting two women of differing race. Children's choices of giving to either the White or Black individual were recorded.

3.1. Methods

3.1.1. Participants

Twenty-four full-term 2.5–3-year-old White children participated in the study (12 females; mean age 32.5 months; range 29.5–35.5 months).

3.1.2. Materials

The same Black and White individuals featured in Experiment 1 served as stimuli. Static images of the two individuals were projected approximately life-size on screen, with the child seated at the table in front of the screen. A table was positioned 50 cm from the screen, to allow for an experimenter to move between the screen and the table. On the table were two cardboard boxes (20 cm³) with a felt opening on top, and a felt opening on the side towards the screen, such that a child could place something in the box on the top side, and an experimenter could remove the item from the back of the box. Boxes were placed on the left and right side of the table, equidistant from the child.

3.1.3. Procedure

Children were first instructed in the giving game. An experimenter sat facing the child, between the screen and the table. A series of pairs of cartoon animals appeared on the left and right side of the screen, and children were shown that when a "present" (different colored toy balls) was placed in one of the two boxes, the present would subsequently appear on screen, and reward the animal on the corresponding side of the screen. During two test trials, children were shown an image of the two individuals side-by-side on screen, at which point children were instructed to "give a present" to one of the two individuals. When the child placed the present in one of the two boxes, a chime noise was played, the present appeared on the screen, and the individual on the corresponding side of the screen smiled. Lateral position of presentation (White individual on the left or right) was counterbalanced across children.

3.2. Results and discussion

Children gave presents equally to the two individuals who differed in racial group membership ($M_{\text{White}} = 1.00$, $SE = .12$; $M_{\text{Black}} = .96$, $SE = .11$; Fig. 2, center). A non-parametric test confirmed that children did not selectively give to one individual over the other: four children gave more to the White individual, four children gave more to the Black individual, and 16 children gave equally ($p = n.s.$, 2-tailed sign test). To test whether children's performance reflected a strategy of equal giving across the two trials, a further analysis focused on just the first trial, when children had no way to know whether a second trial would be offered. On the first trial, 11 children chose to give the present to the White individual, 12 children chose the Black individual, and one child did not make a choice. Again, their patterns of response on the first trial did not differ from chance ($p = n.s.$, 2-tailed sign test). Thus, the absence of race-based giving preferences cannot be explained as a strategy of egalitarian giving. The findings suggest, instead, that 2.5-year-old children's giving is influenced by the language of their potential recipients but not by the recipients' race.

Although past research demonstrates clear evidence of majority-race preschool-aged children's social preferences based on race, most findings are reported beginning at age 4 or 5, and do not necessarily find similarly strong results with 3-year-old children (Abel & Sahinkaya, 1962; Aboud, 2003; Brown & Johnson, 1971; Kircher & Furby, 1971; Stevenson & Stewart, 1958). Recent research investigating 3-year-old children's attention to social categories in guiding their object-based preferences finds that children of this age only marginally attend to race, in contrast to robust attention to gender and age (Shutts et al., 2010). Thus, a failure to find race-based social preferences at 2.5 years is not inconsistent with previous research, and provides further evidence that race-based social preferences may emerge only by the end of the preschool years.

It should be noted that children tested in this sample, as well as in Experiment 1, were exclusively White. Though testing a more diverse group of children would certainly be desirable, if one were to expect to find early race-based preferences, they would most likely be found in White majority-race children (Aboud & Skerry, 1984). The final experiment therefore tested for race-based social preferences in older White children, using the same stimuli presented to infants and toddlers in the first 2 experiments.

4. Experiment 3

Experiment 3 investigated 5–6 year-old children's explicit social preferences for novel individuals who are Black vs. White, using two measures. Children were shown the displays presented to infants and younger children in Experiments 1 and 2. Children were told that these displays were shown to infants, and they were asked which person they thought that infants would prefer, and also which person they would prefer to have as a friend, following the method of Kinzler et al. (2009). Consistent with past research, we predicted that children would select the White individual.

4.1. Participants

Twelve White 5–6-year-old children (mean: 5 years 9 months; range: 5 years, 2 months to 7 years 0 years) participated in the experiment.

4.2. Materials

Images from dependent measures in Experiments 1 (toy offering events) and 2 (static images of each individual) served as stimuli.

4.3. Design and procedure

Children were shown two events. During the toy offering event, children were shown a movie of the White and Black individual smiling, and offering two toys. Children were asked, "These are movies we show to babies. Whom do you think babies will choose to take toys from?" During the static event, children were shown the Black and White individual on screen, and were asked "Which one would you rather be friends with?" The order of the offering and static trials, the order of individuals presented within each trial, and the left–right positions of the two individuals presented on the screen were orthogonally counterbalanced across children. Children's choices were tested against chance (.5) by binomial tests.

4.4. Results and discussion

Across the two test questions, children robustly chose the White individual ($M_{\text{White}} = 1.75$ choices, $SE = .13$; $M_{\text{Black}} = .25$ choices, $SE = .13$). See Fig. 2, right. When shown the toy offering event, 11/12 children chose the White individual ($p < .01$, 2-tailed sign test). When shown the static images and asked whom they preferred as friends, 10/12 children chose the White individual ($p < .05$, 2-tailed sign test). Thus, consistent with past research, kindergarten-aged children demonstrated race-based social preferences. Moreover, children's choices for the own-race individual provide evidence that the race of the particular individuals used in these studies was apparent, and infants' and children's failure to demonstrate race-based social preferences in Experiments 1 and 2 was not due to an unbalanced choice of stimuli.

5. General discussion

Across three experiments, a developmental progression in infants' and children's race-based social preferences was observed. In Experiment 1, White 10-month-old infants accepted toys equally from White and Black individuals. In Experiment 2, White 2.5-year-old children gave toys equally to White and Black individuals. In contrast, when White 5–6-year-old children viewed the same events, they expressed race-based social preferences. These findings cast doubt on the thesis that the same-race looking preferences of younger, majority-race infants are true social preferences. Rather, they suggest that social preferences based on race emerge between 2.5 and 5 years of age.

Several alternative interpretations for the present findings can be rejected, based on the findings themselves and on past research. First, it is unlikely that the absence of race-based preferences at the two younger ages reflects an egalitarian bias leading children to choose the two people equally across trials, masking an existing race-based preference. Although egalitarian responding is sometimes observed in children, it tends to increase, not decrease, with age (Fehr et al., 2008). Moreover, children showed no egalitarian bias towards giving resources to individuals who differ in their native language (Kinzler et al., 2007, *in press*). Finally, in Experiment 2, children showed no preference overall for the own-race individual, and no preference on the first of two giving trials. All these findings cast doubt on the idea that infants and children have an own-race preference that is tempered by a tendency toward egalitarian social behavior.

Second, it is unlikely that infants' and young children's equal patterns of receiving and giving reflect a failure to detect the individuals' race. Children's choices for the own-race individual in Experiment 3 provide evidence that the race of the particular individuals used in these studies was apparent to older children. Moreover, race detection is highly reliable and replicable in even younger infants than those tested here (Bar-Haim et al., 2006; Kelly et al., 2005). Indeed, 3-month-old infants respond to race in faces that are presented under far more impoverished conditions, when each face is presented only in a single static photograph. Although abilities to discriminate and categorize faces likely increase substantially over infancy and childhood – as suggested by an increase over the first year of life in infants' relative recognition memory for familiar-race, over unfamiliar-race faces (Kelly et al., 2007) – the present findings are not likely due to a simple failure of perceptual discrimination.

Third, it is unlikely that infants' and young children's equal patterns of receiving and giving reflect limitations of the methods used to test for race-based social preferences. Experiments 1 and 2 tested for these preferences using the same methods that provided evidence for social preferences based on language in infants and children of the same age as those in the present studies (Kinzler et al., 2007, *in press*). Of course, it is always possible that infants and young children have some incipient social preferences among people of different races that the present displays and methods failed to reveal. If such preferences exist, however, they are fragile in comparison to infants' preferences among speakers of different languages.

The contrasting effects of language and race on infants' social preferences are of theoretical importance, for they suggest that these two dimensions of familiarity are not equal to infants. Although young infants look longer at both individuals who previously spoke in a native language with a native accent (Kinzler et al., 2007), and individuals who are of a familiar race (Bar-Haim et al., 2006; Kelly et al., 2005), early looking preferences based on language and race may reflect two different phenomena. The former may be a sign of a social preference for individuals in one's native language group. In contrast, the latter may be a sign of visual familiarity, allowing for more efficient or deeper perceptual processing of a face with little or no

consequence for early social interactions. It would be interesting to further explore potential relationships and discontinuities between infants' and children's face processing and social preferences.

Although 5–6 year-old children showed preferences based on race in Experiment 3, other research has compared race and language preferences directly at this age, providing evidence that accent trumps race in children's explicit social judgments (Kinzler et al., 2009). Though by 5 years of age children profess explicit preferences for both native-accented individuals and own-race individuals in isolation, when accent is pitted against race, White children prefer to be friends with someone who is Black and speaks in a native accent, rather than someone who is White and speaks with a foreign accent (Kinzler et al., 2009). Throughout the preschool years, therefore, language provides a more powerful basis for social categorization and preference than does race.

There are several reasons why language may trump race in its early social salience. First, children have a “head start” in their familiarization to language over race. From birth, infants prefer the sound of their native language due to input they received in the womb (Mehler et al., 1988; Moon, Cooper, & Fifer, 1993), whereas it is not until 3 months of age that infants prefer own-race faces (Kelly et al., 2005). Furthermore, as discussed above, there is reason to think that the language with which people speak may have carried greater weight in denoting group membership throughout our evolutionary history than did skin color. Though neighboring groups in ancient times likely spoke with different accents and dialects, they likely didn't look very different in terms of their race (Baker, 2001; Kurzban et al., 2001). Thus, cognitive evolution may have favored attention to language or dialect as a valid marker of coalitional group membership (Henrich & Henrich, 2007; McElreath et al., 2003), and this predisposition may be reflected in modern-day infants' early social preferences.

Finally, and perhaps most speculatively, attention to language over race may reflect an “essentialist bias,” in which language is treated by children as an “inner” property, whereas race is treated as a less important “outer” property of individuals. This hypothesis accords with research showing that children's attention to categorical information can outweigh attention to perceptual information when reasoning about other social categories such as gender and ethnicity (Gelman, Collman, & Maccoby, 1986; Diesendruck & haLevi, 2006), and that even in infancy, children see internal features of an individual as being more predictive of his behaviors than external properties (Newman, Herrmann, Wynn, & Keil, 2008). These explanations are not inconsistent with one another, and may in fact work together to explain the phenomena at hand. In particular, an essentialist bias may be a proximate mechanism that mediates the ultimate adaptive mechanism for monitoring meaningful social groups.

The present research raises questions about the potential malleability of early social biases. Infants and toddlers in Experiments 1 and 2 do not attend to race in guiding their early interactions, but 5-year-old children shown the same stimuli prefer individuals of their own race

almost unanimously. The finding that race-based preferences emerge over childhood suggests that they may not be mandatory, but rather may emerge as a result of exposure to racially stratified societies in which race is often a marker of group membership. Children may be inclined to group the world into human kinds (Hirschfeld, 1996), or ingroups and outgroups (Dunham, Baron, & Banaji, 2008); nonetheless, children may not view race as a mandatory variable by which groups are determined in all environments. Future research therefore should investigate the potential malleability of early social preferences as a result of exposure to diverse environments. The present research provides a note of optimism that later race-based social preferences may not be a predetermined outcome of any and all social worlds.

Acknowledgments

We thank Emmanuel Dupoux and Marine Buon for helpful discussion and assistance in the creation of the toy giving method.
